Abstract

The combustion of metallic particles is analogous to the combustion of hydrocarbon particles and the particle burn time can be related to its diametric length. The relationship is called ‘d’ law and represented as \( t_b = d^2 \). From the physics aspect, many deviations from the established laws at the bulk scale have been reported. As the ignition temperature of energetic nanomaterials is more sensitive to the passivation layer and the external heating conditions, and the burning time of nanomaterials is deviated from the conventional \( d^2 \) law. Due to the variation of certain parameters such as the particles size distribution, agglomeration, morphology, level of contamination and initial particle size, the correct and precise value of the exponent is difficult to find. Consequently, there’s no universal law for the burn time and a variant of the \( d^x \) law is always proposed whose exponent is less than 2 (~1.3-1.7). In this research, combustion experiments are performed using a Bunsen burner in a particle-laden methane stream and the relationship of particle burning time with particle diameter is found to be \( t_b \sim d^{1.2} \). The combustion process of the various particles is captured using a high speed video camera. The average values of extinction time for Si (720 nm) and Si (1000 nm) are 11.4 ms and 17.2 ms, respectively. It is also observed that the nanoparticles are more reactive than the microsized particles. The average velocity flow fields of the silicon, iron and aluminum particles are also investigated using PIV technique. Before and after the experiments, the particles are characterised using dynamic light scattering (DLS), scanning electron microscopy (SEM), Energy-dispersive X-ray spectroscopy (EDS) and transmission electron microscopy (TEM).

Keywords: Reactive Nanomaterials, Particle Combustion, D Law, PIV, Particle Characterisation
1. Introduction

The combustion of energetic metallic particles or particle suspensions have long been the area of interest in the combustion research community. Enormous research has been conducted to understand the mechanism of combustion of metallic particles either to improve the burning rate [1-3] or inhibit it for hazard prevention [4, 5]. The physics of oxidation of fine particles (nanoparticles or sometimes micro-sized particles exhibiting size-dependent behaviours) have been found to be different to that of conventional-sized particles (i.e. > 50 micrometres) [6]. As the physical and thermodynamical properties of the fine powders are different, the models describing the oxidation of conventional-sized powders make certain assumptions such that at any given instant the growth of oxide depends upon the diffusion of a single species etc. [7]. Such assumptions are not valid for the fine particles. For conventional-sized particles, the diffusion based oxidation is a good assumption, but for fine particles, the reaction is more likely to be kinetically controlled [6, 8].

The metals are normally ignited after achieving their boiling point. The volatility of the metal oxide relative to the metal and overall energy available for the gasification of both the metal and its oxide are very important factors in the phenomenological understanding of metal combustion. There are two possibilities for the combustion [9, 10] that 1) the metal relative to its oxide is volatile and the energy released during the reaction is sufficient to vaporize the oxide. This ensures that the combustion is homogenous and proceeds in the vapour phase via the diffusion of ions, 2) the metal relative to its oxide is non-volatile and oxidation energy is not enough to vaporize it. The combustion will be heterogeneous and proceed purely in the condensed phase [11]. Von Grosse and Conway [12] found that the flame temperature of the metal is limited to the volatilization-dissociation or boiling point of the oxide. If the oxide’s volatilization temperature is higher than the boiling point of the metal, the combustion will proceed heterogeneously, i.e., in the condensed phase, on the surface of metal particles. On the other hand, when the heat of reaction is sufficient to transform both the oxide and the metal into gas, the combustion will proceed in the vapour phase. This is called Glassman’s criteria for vapour phase combustion [58].

Glassman et al. [13] proposed that the combustion of conventional-sized aluminium particles is analogous to the combustion of hydrocarbon particles, and the burn time is related to the square of its diametric length, known as $d^2$ law. Many differences have been reported on the combustion behaviour of fine particles and that of the conventional particles. The burning time of fine particles is a function of the particle morphology and the temperature and pressure of the environment [14]. Olsen and Beckstead [15, 16] observed that the burning time ($t_b$) of microsized particles (40-70 μm) was weakly related to the temperature of the surrounding gas. In the case of nanosized particles, Bazyn et al. [17] showed a strong dependence on the pressure of the surrounding gas, which concluded that the combustion process was kinetically controlled. Many studies [18-20] show that when the diameter of the particle becomes very small, the exponent of the conventional law of burn time, i.e., $t_b = \beta d^2$ becomes less than 2. However, due to the agglomeration and non-uniform dimensions of these nanoparticles, an accurate exponent number is not easy to find.

Various techniques including lasers, shocks, flashes and gas burners [21-23] have been developed to initiate the ignition. The combustion history of the particles is often tracked by the high speed cameras and the morphology is examined with the help of Electron Microscopes (EMs). The Particle Imaging Velocimetry (PIV) is used to measure the flame flow and analyse its characteristics [24]. In this article combustion experiments are performed using a Bunsen burner in a particle-laden methane stream and the relationship of particle burning time with particle
diameter is reported. The particles are characterised using DLS, SEM, EDS and TEM. A high speed video camera is used to capture the combustion process of the particles, and PIV technique is used to investigate the average velocity flow fields of the silicon, iron and aluminum particles. From the particle extinction time, the exponent of relationship the of $t_b = d^n$ is obtained.

2. Materials and Methods

2.1. Materials

Al, Si and Fe were used in the combustion experimentation. The physical characteristics of nAl have already been reported in ref. [25]. SEM and TEM images of nAl are shown in Figure 1.

![Figure 1](image.png)

Figure 1. SEM (a) and TEM (b) images of n-Aluminum particles show that the particles are spherical and agglomerated (before combustion).

Two types of Si particles were purchased from Nanostructure and Amorphous Materials Ltd (USA), with a nominal particle size of 50 nm and 1000 nm respectively. However the 50-nm nanoparticles come with heavy agglomerations. To reflect the particle morphology upon combustion, some Si samples were dispersed into ethanol without any mechanical or chemical aid, and its size distribution is measured by DLS, as shown in Figure 2. The particles size distribution is in the range of 600 to 1000 nanometer, peaking at ~ 720 nm, which is much larger than the primary particle size of ~50nm. Iron powder having a grade Fe300 was purchased from William Rowland Ltd. The Fe powder has diameter ranges from 45-75 μm and an average density of 2.8-3.0 g/cm$^3$. It was 99% pure and contained some trace elements like C (0.01%), S (0.025%) and O₂ (0.15%). All the particles were mixed with natural gas (CH$_4$, 98%) and were combusted using a burner in the atmosphere of air. The particles were characterised with SEM, TEM and EDS employing the methods discussed in detail in the previous work [25].
2.2. Aerosol generation assembly
The experimental set up consists of a methane delivery assembly. The particles were mixed with the methane stream through a belt conveying system, where the particles were loaded from a hopper onto a belt, which was driven by an electric motor (12 V). The amount of particles added into the gas stream was adjusted by the speed of the motor. For the experimental results reported below, the amount of methane was regulated at 2 l/min to ensure the uniform flow rate of the gas.

2.3. Bunsen burner
Commercially available Bunsen type burner was used to analyse the combustion characteristics of the particles/methane/air. A continuous particle laden stream of methane gas from the feeder was supplied to the burner through a silicon tube having a diameter of 6 mm. Once the steady flow was achieved, the particles were ignited and were combusted under the atmospheric conditions. The burner was air cooled because the experiments were last only for a few minutes.

![Figure 3. Schematic diagram of experimental set up (R-Regulator; V-Meter valve; A-Aerosol generation assembly; M- Driving motor; C- Control circuit and B-Bunsen burner.)](image)
2.4. Image capture
The combustion of the particles was recorded and subsequently interpreted with the help of a high speed video camera (Phantom V2.3) recording at a frequency of 1000 Hz with 256 by 128 pixel array. The recording was started once the flame became stable. The distance to pixel ratio (spatial resolution) was calculated as 14.5, 14.9 and 16.7 for Si (720 nm), Si (1 µm) and Fe (45-75 µm), respectively. The capture time in all experiments was maintained constant at 1 ms. The captured images were binarised using J-image software.

2.5. Particle image velocimetry (PIV) measurement
The combustion velocity, burning times and reactivity/ignitibility of various particles are quantified with the particle image velocimetry technique. The velocity profile and flow vectors of the combusted particles were processed using the PIVview2C software. To achieve time-averaged results with higher quality, the average speed of the particles was calculated by processing 100 images (50 image pairs). Only axial component of the velocity was determined. For image pair data processing, a window size of 32x32 (pixel) having a step size of 16x16 (pixel) was used. Images were evaluated with a direct cross (non-FFT) correlation. Multiple pass interrogation method with number of iterations 3-passes was used. The velocity vector and particle flow field was smoothed with a smooth kernel width (in nodes) of 1.0. No filtering or interpolation was done to fill in the missing vectors.

3. Results and Discussion

3.1. Particle characterisation
SEM images of the particles after their combustion are shown in Figure 4 and the EDS analyses are summarised in Table 1.

From the SEM images, it is observed that nanoparticles of Al and Si are still kept spherical. On the other hand, micrometric particles of Fe and Si are changed to big agglomerates of non-uniform shapes. Interestingly the EDS results of both nanometric particles (Al and Si) show that it contains 55.46% (for Al) and 29.12% (for Si) of carbon. Contrary to that, the EDS of the micrometric particles does not show any signal of carbon. This means that during the experiment fewer Fe particles were burnt.

3.2. Combustion experiments
The particles are ignited/ combusted at atmospheric conditions in the stream of natural gas/air using a conventional Bunsen burner, which is a simple system that allows greater control over the combustion parameters.

The particles are ignited after passing through the inner core having the highest flame temperature. Typical particle combustion image showing distinct zones of the flame is presented in Figure 5.
3.3. Comparison of reactivities of Si particles
With the decrease of particle diameter, the specific surface area of the particle increases. This increases the contact points among the reactants and the particles. Consequently, the reactivity of the nano particles is higher than that of the micro particles. To reflect the particle morphology upon combustion, the peak particle size, i.e., 720 nm, rather than the primary particle size as supplied by the manufacturer. In the experiment particles of Si having 720 nm and 1 µm diameter are combusted at the same experimental conditions, and their combustion behaviour is compared in Figure 6.
Figure 6. Binarised images of the particles of Si (720 nm (a) and 1\,\mu m (b) ) showing the higher ignitibility (reactivity) of the particles having a smaller diameter.

The pin stubs for collection of the combusted particles were mounted over the flame. It can be easily discerned from Figure 6 that the particles having a smaller diameter are characterised with higher reactivity as more particles are combusted during the combustion process. On the other hand, small number of particles (Si 1\,\mu m) is combusted due to which the signal of carbon in the EDS results is missing.

3.4. PIV and extinction time results

It is very important to have detailed knowledge of particle combustion behaviour particularly its combustion velocity in relation to its ignition and burning time. PIV experiments are used to find out the velocity profiles of the burning particles. A series of PIV experiments were performed to calculate and compare the flow fields and speeds of the various particles, shown in Figure 7 and Figure 8.
Figure 7. Showing the results of PIV of an image pair of Si (720 nm) particles, a) velocity vector field; b) average axial components of velocity.
Figure 8. Showing the PIV results of image pairs of Si (1000 nm) and Fe (45-75 μm) particles, a) velocity vector field of Si; b) average components of velocity of Si; c) velocity vector field of Fe; d) average components of velocity of Fe.
From Figure 7 and Figure 8, it can be observed that the ignitability/reactivity of the particles increase with the decrease of the diameter. The results of PIV profiles of Fe and Si having micrometric dimensions are similar to each other. It can be seen that the particles were ignited after passing through the tip of the internal cone which is the point of maximum temperature in the flame. In the post flame zone (outer cone) the particles extinguish after travelling some distance.

The mean speed profile of 50 image pairs are represented and compared in Figure 9. The average speeds of Si (720 nm), Si (1 μm) and Fe (45-75 μm) in the methane stream are 1.18 m/s, 1.15 m/s and 1.71 m/s, respectively.

The extinction times for 100 particles are calculated by tracking their motion. The average values of extinction time for Si (720 nm) and Si (1000 nm) are 11.4 ms and 17.2 ms, respectively. If assuming the extinction time as the burning time, the relationship of $t_b \sim d^{1.2}$ can be obtained. The exponent value is similar to that observed by Friedman and Maccek (1.2-1.5) [26].

The diffusion limited droplet combustion theory predicts that the combustion time is related to the square of particle diameter, i.e., $d^2$ law. However, with the decrease of particles size, the diffusion limited oxidation assumption becomes invalid and the oxidation transitions towards kinetically controlled. Various $d^n$ relationships are presented in the literature, depending upon the particles size, level of agglomeration, combustion and experimental conditions. These experiments demonstrate the large difference between conventional-sized particles and fine particles.

4. Conclusions

This research provides an investigation of the combustion characteristics of three particles, Al, Fe and Si, having variable dimensions in the methane/air stream in a Bunsen burner setup. The following conclusions are made,
- Most of the particles are burned after passing through the inner flame cone.
- The chemical compositional analyses (EDS) show no carbon signals for the micrometric particle, which suggests small number of particles are burned during the experiment.
- The comparison of silicon particle with different sizes shows that the reactivity of the particle increases with the decrease of the diameter.
- The results clearly demonstrate that the conventional d² law is not applicable to the fine particles.
